ABSTRACT

We use the NIHAO galaxy formation simulations to make predictions for the baryonic budget in present day galaxies ranging from dwarf ($M_{\text{tot}} \sim 10^{10} M_{\odot}$) to Milky Way ($M_{\text{tot}} \sim 10^{12} M_{\odot}$) masses. The sample is made of 88 independent high resolution cosmological zoom-in simulations. NIHAO galaxies reproduce key properties of observed galaxies, such as the stellar mass vs halo mass and cold gas vs stellar mass relations. Thus they make plausible predictions for the baryon budget. We present the mass fractions of stars, cold gas ($T < 10^4 \text{K}$), cool gas ($10^4 < T < 10^5 \text{K}$), warm-hot gas ($10^5 < T < 10^7 \text{K}$), and hot gas ($10^7 \text{K} < T$), inside the virial radius, R_{200} . Compared to the predicted baryon mass, using the dark halo mass and the universal baryon fraction, $f_b \equiv \Omega_b/\Omega_m = 0.15$, we find that for all of our haloes, the missing mass is not just outside the virial radius R_{vir} , it has been relocated past $2R_{\text{vir}}$. Haloes of mass $M_{\text{tot}} \sim 10^{10} M_{\odot}$ are missing $\sim 90\%$ of their baryons. **Cool gas dominates the fraction of total baryons surrounding galaxies up to several times of virial radius, in which most of them are well outside of virial radius.** More massive haloes ($M_{\text{tot}} \sim 10^{12} M_{\odot}$) retain a higher fraction of their baryons, with $\sim 30\%$ missing, consistent with observational estimates.

Key words: galaxies: evolution – galaxies: formation – galaxies: dwarf – galaxies: spiral – methods: numerical – cosmology: theory

1 INTRODUCTION

Cosmic structure formation has redistributed the baryons from a nearly uniformly distributed plasma into a variety of states, including stars, stellar remnants, cold (atomic and molecular) gas, and hot (ionized) gas. The theories of galaxy formation can predict the amount of mass in these different states, which can in turn be tested by observational constraints.

On cosmological scales, the ratio between the total baryonic and gravitating mass is measured to be $f_b \equiv \Omega_b/\Omega_m \simeq 0.16$ (The Planck Collaboration 2014). However, the cold baryonic mass density implied by several galaxy baryon estimates is only 3-8% of the big bang nucleosynthesis expectation (Persic & Salucci 1992; Fukugita et al. 1998; Bell et al. 2003; McGaugh et al. 2010). The majority of the cosmic baryons are thought to be in the form of hot gas around or between galaxies (Cen & Ostriker 1999). Until recently only a fraction of these baryons had been detected

(Bregman 2007; Shull et al. 2012). This discrepancy is referred to as the “missing baryon problem”. **Several theoretical research with cosmological simulation have constrained the phase status and cosmological environments of the potential reservoir to hide the missing baryons (Yoshida et al. 2005; He et al. 2005; Davé et al. 2010; Zhu et al. 2011; Haider et al. 2016).**

The circum galactic medium (CGM) is one major potential reservoir of missing baryons in halo scale. Recent advances in the detection of gas in the CGM have come from the COS survey (Tumlinson et al. 2011, 2013; Thom et al. 2012; Werk et al. 2012, 2013). On the scale of Milky Way mass haloes $M_{\text{tot}} \sim 10^{12} M_{\odot}$ a significant amount of warm ($10^4 < T < 10^7 \text{K}$) gas has been detected (Werk et al. 2014), accounting for 33-88% of the baryon budget. In the future such observations will be extended to a wider range of halo masses. **To understand the physical properties of CGM and the origins of components in each phase has been shown to be able to test the impact of feedback models (Sharma et al. 2012; Marasco et al. 2013). Daveé (2009) predicted galac-**

tic halo baryon fractions of galaxies with halo mass range from $10^{11}M_{\odot}$ to $10^{13}M_{\odot}$ cosmological hydrodynamic simulations with a well-constrained model for galactic outflow, which found that, without outflow model, the baryon fraction is roughly the cosmic baryonic fraction, but with outflow in the simulation, the baryon fraction is increasingly suppressed in haloes to lower mass. By comparing results at $z=3$ and $z=0$, they showed the large haloes remove their baryons at early epoch while small haloes lose baryons more recently due to wind material takes longer to return to low-mass galaxies than high-mass galaxies. Sokolowska et al. (2016) studied halo gas of three Milky way-sized galaxies using cosmological zoom-in simulations. They found that most of missing baryons actually resides in warm-hot and hot gas which contribute to 80% of the total gas reservoir. The recovered baryon fraction within 3 virial radii is 90% and can solve the missing baryon problem. The warm-hot medium is sensitive to the feedback model so that the reliable spatial mapping of warm-hot medium will provide a stringent test for feedback models.

In this paper we make predictions for the baryonic budget for stars, cold, warm and hot gas in and around the virial radius of haloes of mass ranging from $M_{\text{tot}} \sim 10^{10}M_{\odot}$ to $10^{12}M_{\odot}$. We use a sample of 88 zoom-in galaxy formation simulations from the NIHAO project. NIHAO galaxies are consistent with the stellar mass vs halo mass relations from halo abundance matching since redshift $z \sim 4$ (Wang et al. 2015), the galaxy star formation rate vs stellar mass relation since $z \sim 4$ (Wang et al. 2015), and the cold gas mass vs stellar mass relation at $z \sim 0$ (Stinson et al. 2015). Therefore, the simulations make plausible predictions for the mass fractions and physical locations of the warm and hot gas components. We find that all the haloes contain less baryons than expected according to the cosmic baryonic fraction, but the missing fraction is strongly mass dependent.

This paper is organized as follows: The cosmological hydrodynamical simulations including star formation and feedback are briefly described in §2; In §3 we present the results including the baryonic budget, baryon distribution, and a comparison with observations; §4 gives a summary of our results.

2 SIMULATIONS

In this study we use simulations from the NIHAO (Numerical Investigation of a Hundred Astrophysical Objects) project (Wang et al. 2015). The initial conditions are created to keep the same numerical resolution across the whole mass range with typically a million dark matter particles inside the virial radius of the target halo at redshift $z = 0$. The halos to be re-simulated at higher resolution with baryons have been extracted from 3 different pure N-body simulations with a box size of 60, 20 and 15 h^{-1} Mpc respectively. We adopted the latest compilation of cosmological parameters from the Planck satellite (the Planck Collaboration et al. 2014). More information on the collisionless parent simulations and sample selection can be found in Dutton & Macciò (2014) and Wang et al. (2015).

We use the SPH hydrodynamics code GASOLINE (Wadsley et al. 2004), with a revised treatment of hydrodynamics as described in Keller et al. (2014). The code includes a sub-grid model for turbulent mixing of metal and energy (Wadsley et al. 2008), heating and cooling include photoelectric heating of dust grains, ultraviolet (UV) heating and ionization and cooling due to hydrogen, helium and metals (Shen et al. 2010). The star formation and feedback modeling follows what was used in the MaGICC simulations (Stinson et al. 2013). There are two small changes in NIHAO simulations: The change in number of neighbors and the new combination of softening length and particle mass increases the threshold for star formation from 9.3 to 10.3 cm^{-3} , the increase of pre-SN feedback efficiency ϵ_{ESF} , from 0.1 to 0.13. The more detail on star formation and feedback modeling can be found in Wang et al. (2015).

3 BARYON BUDGET

We define the fiducial baryonic mass as:

$$M_b \equiv M_b(R_{200}) = \frac{f_b}{1 - f_b} M_{\text{dm}}(R_{200}) \quad (1)$$

where the M_{dm} is the total dark matter mass in the halo, and the $f_b = \Omega_b/\Omega_m \sim 0.15$ is the cosmic baryon fraction (the ratio between baryon density and mass density including baryonic mass plus dark matter), so that the M_b is the baryonic mass inside the virial radius if the baryons follow the dark matter closely.

Fig. 1 shows the ratio between the mass of each baryon component inside the virial radius to the fiducial baryonic mass for the most massive galaxy in each zoom-in region. We present the fractions of total stellar mass (blue points), and the total baryonic mass including stellar mass plus gas mass (green points). For the stellar mass fraction we also show the relations from the halo abundance matching (Moster et al. 2013; Behroozi et al. 2013; Kravtsov et al. 2014). The grey area is the one sigma scatter around the mean value from Kravtsov et al. (2014).

We tried to capture the behaviour of the baryonic mass fraction as a function of the halo mass using a double power law formula:

$$\frac{f}{f_0} = \left(\frac{M_{200}}{\mathcal{M}_0} \right)^{\alpha} \left\{ 0.5 \left[1 + \left(\frac{M_{200}}{\mathcal{M}_0} \right)^{\gamma} \right] \right\}^{\frac{\beta - \alpha}{\gamma}}. \quad (2)$$

In this formula, the lower and higher mass ends have logarithmic slope α and β , respectively, while γ regulates how sharp the transition is from the lower to the higher ends. The best fit parameters are as follows:

$$\begin{aligned} \mathcal{M}_0 &= 6.76 \times 10^{10} \\ f_0 &= 0.336 \\ \alpha &= 0.684 \\ \beta &= 0.205 \\ \gamma &= 3.40 \end{aligned} \quad (3)$$

The green shaded region indicates the scatter about the best fit line, **which are 0.151 for haloes with mass in the range of $3 \times 10^9 M_{\odot} < M_{200} < 2 \times 10^{10} M_{\odot}$, 0.236 for halo mass in $2 \times 10^{10} M_{\odot} < M_{200} < 7 \times 10^{10} M_{\odot}$, 0.125 for halo**

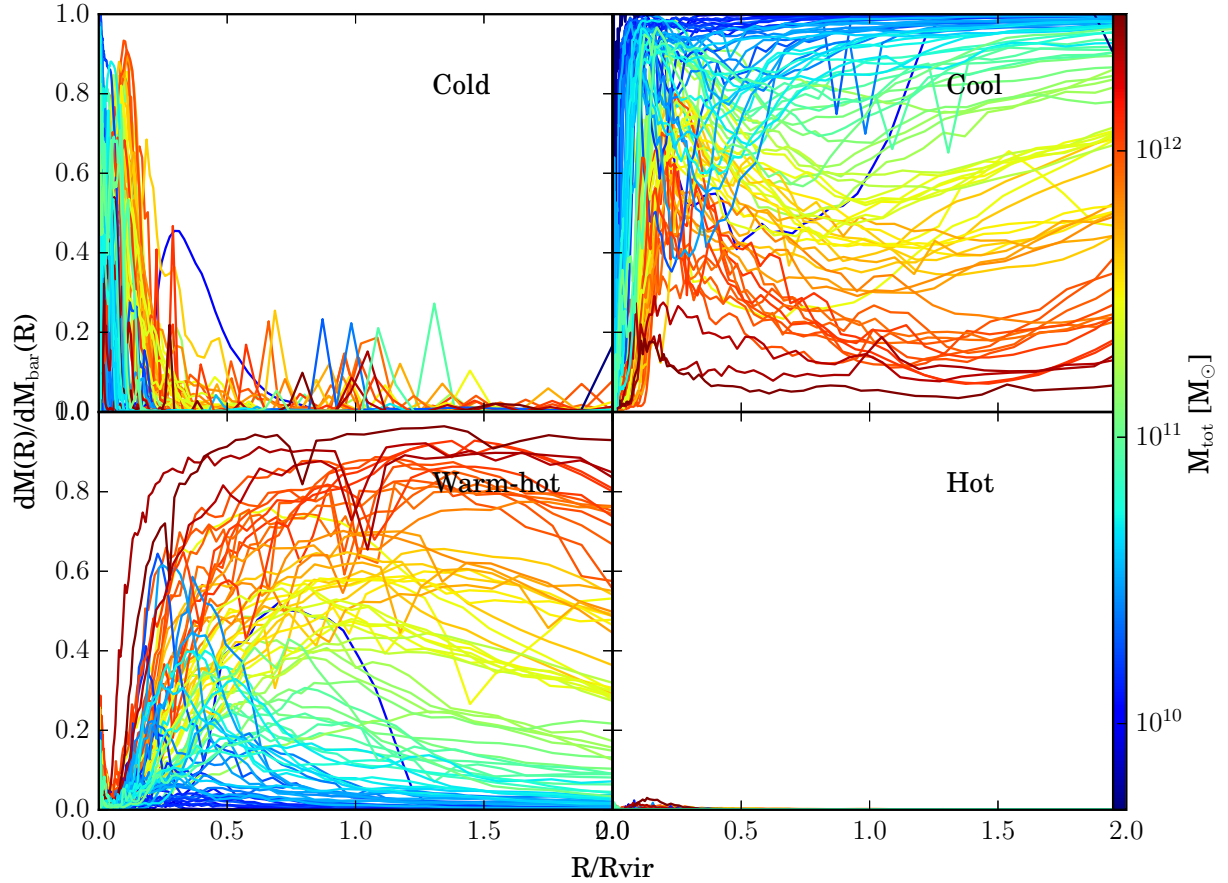

Figure 2. Radial profile of the mass fraction of the gas in each phase to total baryon mass in each radial bin at $z=0$ for all galaxies in NIHAO sample. Each solid line is from one galaxy and color coded with the halo mass.

mass in $7 \times 10^{10} M_{\odot} < M_{200} < 3 \times 10^{11} M_{\odot}$ and 0.0518 for halo mass in $3 \times 10^{11} M_{\odot} < M_{200} < 3.5 \times 10^{12} M_{\odot}$.

The trends of each component fraction are similar, in that the fractions are relatively low in low mass haloes, and increase as the halo mass increases. The main difference between the different components is the slope, with the baryonic mass fraction having a shallower slope than the stellar mass fraction. This is because in low mass haloes ($M_{\text{tot}} \sim 10^{10} M_{\odot}$) most of the baryons are in the form of gas, while in the highest mass haloes we study ($M_{\text{tot}} \sim 10^{12} M_{\odot}$) there are roughly equal amounts of stars and gas.

Fig. 1 shows that all haloes in our study contain less than the universal fraction of baryons. The upper panel uses a linear y-axis scale, which highlights the large amount of baryons that are missing, especially in low mass haloes. The logarithmic scale in the lower panel highlights the power-law nature of the relations.

Since the haloes we study are above the mass where the cosmic UV background prevents gas from cooling, the missing baryons have most likely been ejected from the central galaxies in supernova/stellar feedback driven winds. Although the lower mass galaxies have converted a smaller fraction of their available baryons into stars, and hence there

is proportionally less energy available to drive an outflow, they have expelled a larger fraction of their baryons, consistent with expectations from energy driven gas outflows (e.g., Dutton 2012).

3.1 Mass budget of the corona

In Fig. 2, we present the radial distribution of gas in different phases normalized to the total baryon mass in corresponding radial bins at $z=0$. All simulations share a common attribute. The cold gas ($T < 10^4$ K) in corona mostly locates in very center region ($R < 0.5 R_{\text{vir}}$) where most stars in galaxies form. The cool ($10^4 \text{ K} < T < 10^5 \text{ K}$) and warm-hot ($10^5 \text{ K} < T < 10^7 \text{ K}$) gas expand to large distance contrastly, the fractions keep constant till 2 times R_{vir} . The hot gas ($T > 10^7 \text{ K}$) is minority in corona for all galaxies in NIHAO sample, the maximum of the fraction of hot gas is less than 5%.

Despite these similarities, we find considerably high proportion of cool gas for lower mass galaxies ($M_{\text{tot}} < 10^{11} M_{\odot}$) in the whole corona region. For higher mass galaxies, warm-hot gas dominates the

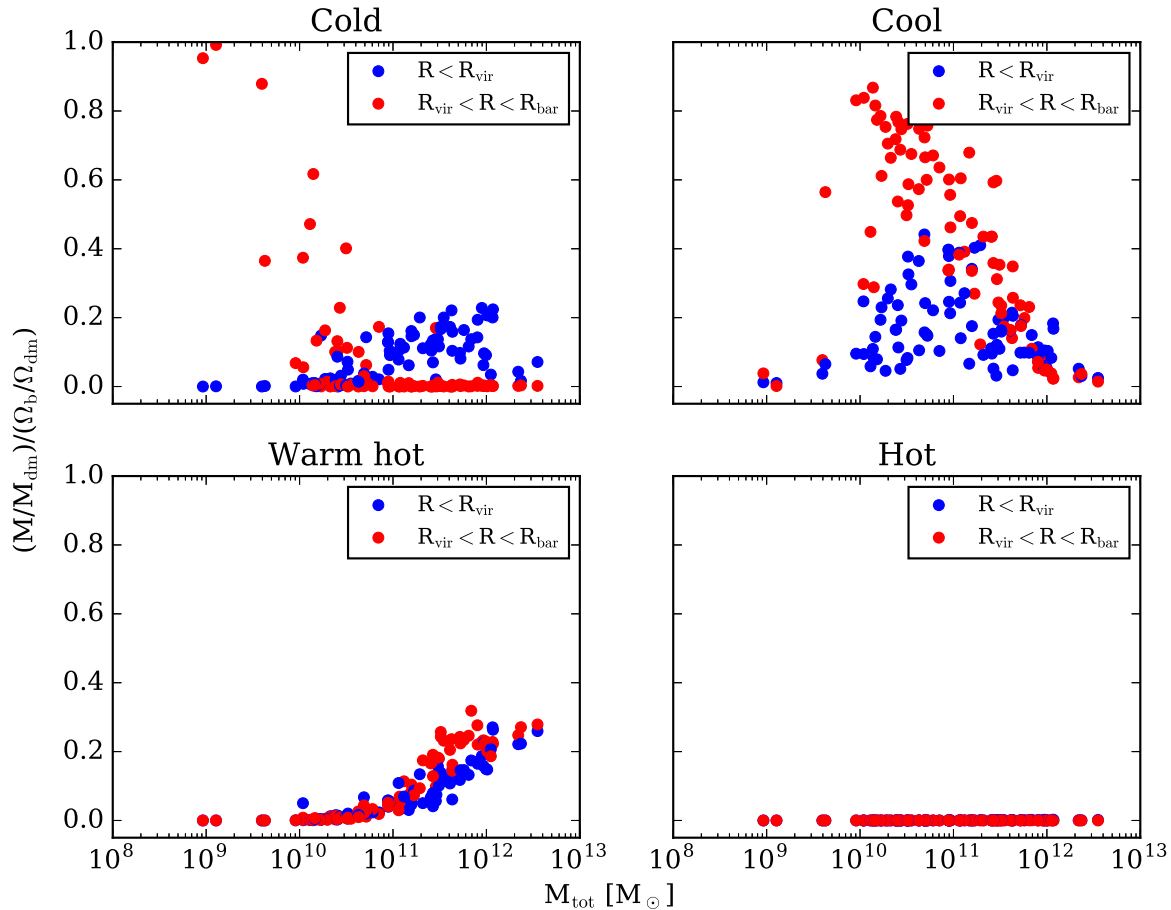

Figure 5. Mass fraction of gas mass in four phases to the fiducial baryonic mass within virial radius. The blue points are mass fraction for the gas inside virial radius and the red points are gas between virial radius and baryon radius.

corona which signals higher efficiency of feedback. Even beyond virial radius, the cool and warm-hot gas has similar features as the gas within virial radius which reveals the gas surrounding galaxies within large distance is the major reservoir of baryons.

3.2 Where are the missing baryons?

Fig. 3 shows the mass ratio profiles of total baryons for each simulation. Here the y-axis is the ratio between the baryonic to dark matter mass, $M_b(< R)/M_{dm}(< R)$, enclosed within a sphere of radius, R , normalized by the cosmic baryon-to-dark matter ratio, Ω_b/Ω_{dm} .

Each solid curve represents a halo, and the curves are colored by their halo mass (red for high masses to blue for low masses). Broadly speaking, the curves have a similar shape, with a normalization that depends on halo mass. They have a cusp in the central region where the stars and cold gas dominate, then become flat in the outer region. More massive haloes have higher baryon fractions at all radii. At small radii, the baryon to dark matter ratio is higher than the cosmic value due to gas dissipation. Even

beyond the virial radius, there is little change in the baryon fraction up to 2 virial radii. We thus conclude that the missing baryons are well outside of the virial radius.

To find out how far the baryons escape, we measured the baryon radius within which the total baryon mass equals to the fiducial baryonic mass defined by Equ. 1. Fig. 4 illustrates the baryon radius of each galaxy as function of the total mass within virial mass. We find the baryon radius increases as the total mass goes higher generally. In the whole mass range, The baryon radii normalized by corresponding virial radii span a similar range which are from larger than virial radius to more than 5 times virial radius, except there are three galaxies with baryon radii larger than 8 times virial radius. It shows that the normalized distance where the baryons inside virial radius can reach is not sensitive to the halo masses.

In Fig. 5, we calculate the fractions of these four kinds of gas inside virial radius and between virial radius and baryon radius. The upper-left panel shows the fractions of cold gas. The fractions of cold gas between virial radius and baryon radius of galax-

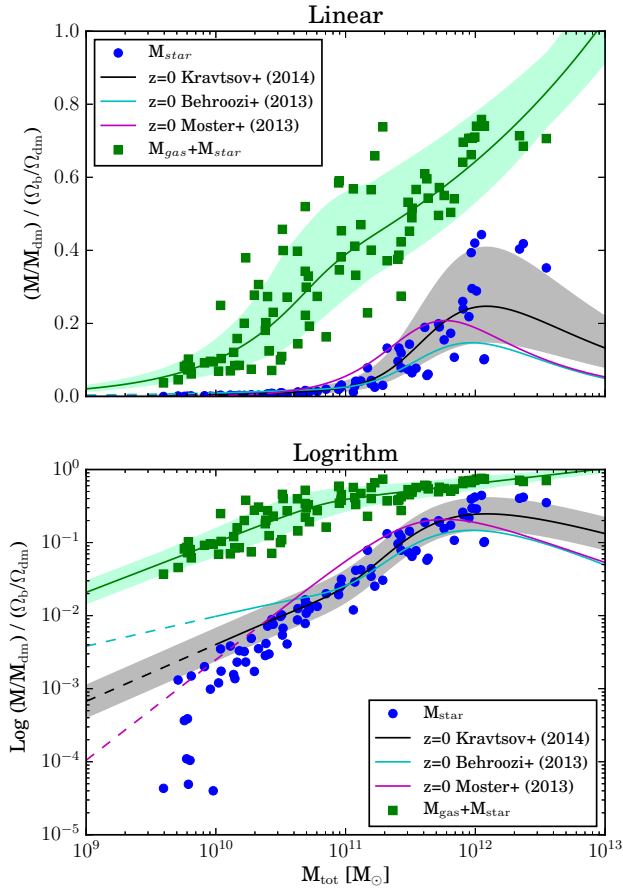

Figure 1. Fractional baryon content of our NIHAO simulations as a function of halo mass. The green points show the ratio between the baryonic mass (stars + gas) inside the virial radius and the total baryonic mass associated with the dark matter halo and the green lines are best fitting lines. The blue points show the corresponding fraction for the stars. The solid green line and shaded region shows a double power-law fit, together with the 1σ scatter. For the stellar mass fraction we show several relations from halo abundance matching. The linear (upper panel) and logarithmic (lower panel) scales emphasize the large amount of “missing” baryons and the low star formation efficiencies.

ies with halo masses in the range between $10^9 M_\odot$ to $10^{10} M_\odot$ are greater than 80%. As the halo mass increase, this fractions go down dramatically, in the mass range between $10^{10} M_\odot$ and $10^{11} M_\odot$ the fractions are less than 20% for most of galaxies and the fractions of galaxies with halo mass above $10^{11} M_\odot$ are almost 0. For the cold gas inside virial radius, the fractions increase gradually as halo masses increase and the maximum fraction is about 20% with halo mass at $10^{12} M_\odot$. The upper-right panel is about the fractions of cool gas. The fractions of cool gas in region outside of virial radius increase from 0 at halo masses are $10^9 M_\odot$ to 80% at halo masses are around $10^{10} M_\odot$ to $10^{11} M_\odot$, then decrease in higher mass range and reach 0 again at halo masses are

Figure 3. Baryon distribution of each galaxy from NIHAO simulations. A comparison of how the baryons distribute in the halo with different masses. The lines are color coded by their halo mass, which show a clear trend that the more massive halo preserve more baryons along the radius.

Figure 4. Baryon radius as function of total mass within virial radius. The points are color coded by the ratio between baryon radius to virial radius of each galaxy.

$10^{12} M_\odot$. The cool gas inside virial radius shares a similar trend but the maximum fraction is about 40% at halo masses are $10^{11} M_\odot$. The fractions for warm-hot gas are shown in the lower-left panel, the trends of the gas inside and outside gas are quite similar which increase as the halo masses increase monotonically and whose maximum values are only 20%. The hot gas shown in the lower-right panel is absolutely minority, the fraction of gas inside baryon radius is almost 0 in the whole halo mass range. We thus conclude that, for the galaxies with halo mass below 10^{11} , the majority of baryons associated with the halo mass within virial radius are in the cold and cool phases, meanwhile are well outside of virial radius, for the gas inside virial radius, the majority is

Figure 6. Baryonic budget (the fraction of different components) of $3.5 \times 10^{11} < M_{200}/M_{\odot} < 3.5 \times 10^{12}$ NIHAO galaxies (blue points with 1σ error bars) compared with observations of $M_{200} = 10^{12.2} M_{\odot}$ galaxies (shaded regions)

cool gas for the galaxies with halo masses are $10^{11} M_{\odot}$ and when halo masses are higher than $10^{11} M_{\odot}$ the fractions of cold gas, cool gas and warm-hot gas are comparable.

3.3 Comparison with Observations of Milky Way mass haloes

Since the CGM is too diffuse to create emission lines, it must be observed using quasar absorption lines. The COS-HALOs survey is filling in details about the $z \sim 0$ CGM (Peeples et al. 2014; Tumlinson et al. 2011, 2013; Werk et al. 2012, 2013, 2014). For the CGM of low-redshift L^* galaxies, Tumlinson et al. (2013) and Peeples et al. (2014) constrain the mass of the warm-hot CGM ($T \sim 10^{5-7}$), Werk et al. (2014) provides a strict lower limit to the mass of cool material ($T \sim 10^{4-5}$) in the CGM of these galaxies. In a study using X-rays, Anderson et al. (2013) place a constraints on the mass of hot gas ($T > 10^7$) residing in the extended hot halos.

In Fig. 6, we show the mean values and standard deviation of the mass fraction of stars and different components of gas in our most massive galaxies ($3.49 \times 10^{11} M_{\odot} < M_{200} < 3.53 \times 10^{12} M_{\odot}$) with blue points and error bars. The gas is assigned to a range of temperature bins: cold gas ($T < 10^4$ K), cool gas (10^4 K $< T < 10^5$ K), warm gas (10^5 K $< T < 10^7$ K) and hot gas ($T > 10^7$ K). The observational constraints are shown with the same colour scheme in Fig. 11 in Werk et al. (2014).

In this plot Werk et al. (2014) provides observational constraints for CGM gas mass that are shown as the shaded bars. The stellar mass range comes from halo abundance matching as described in Kravtsov et al. (2014). The cold disk gas mass comes from Dutton et al. (2011).

The observations and the simulations match well in every phase outside of the cool CGM gas, where the observations find $3\times$ the mass that simulations predict. If the observations are correct, the simulations have either ejected

too far gas that could be cool, or they have created a CGM with the wrong mix of gas temperatures. The total gas fractions (0.39 in COS-HALOs, 0.41 in NIHAO) suggest the latter option. However, Stern et al. (2016) developed a new method to constrain the physical conditions in the cool CGM from measurements of ionic column densities. This new method combined the information available from different during the photoionization modeling, and was applied to the COS-HALOs data, yielding a total cool CGM mass within the virial radius of $1.3 \times 10^{10} M_{\odot}$ which is shown by the green hashed bar in Fig 1 and have good agreement with our prediction. As the Fig. 2 and Fig. 5 show, the cool gas is the most important component in CGM so that the more correct knowledge about physical properties of CGM are necessary to understand the role the CGM on galaxy formation better. As the CGM of lower mass galaxies will soon be observed, Table 1 lists information about CGM mass fractions of the different components of gas in haloes down to a halo mass of $\sim 10^{10} M_{\odot}$.

4 SUMMARY

We have used the NIHAO galaxy simulation suite (Wang et al. 2015) to study the statistical features of the baryonic budget and distribution spanning halo masses of $\sim 10^{10}$ to $\sim 10^{12} M_{\odot}$. NIHAO is a large (currently 88) set of high resolution cosmological hydrodynamical galaxy formation simulations. As shown in previous papers the NIHAO galaxies reproduce several key observed scaling relations. We summarize our results as follows:

- All of the NIHAO haloes have a lower baryon to dark matter ratio, inside the virial radius, than the cosmic baryon fraction.
- Cold gas in most of galaxies (except several low mass galaxies with low SFR) locates within 0.5 times virial radius. The cool gas dominates the corona at low mass range end and the fraction of warm-hot gas increase with the increasing of halo mass and become majority at high mass end.
- The missing baryons in all haloes are beyond 2 virial radii.
- Cool gas is major component in total baryons whose mass is same as the fiducial baryonic mass of total dark matter mass inside virial radius. Most of the cool gas in these baryons locates out of the virial radius.
- Lower mass haloes have lost a larger fraction of their baryons, even though they convert a lower fraction of the baryons into stars.
- For the highest mass haloes in our study $\sim 10^{12} M_{\odot}$ our simulations are consistent with the observed fractions of stars, cold gas, warm and hot gas.
- We underpredict the cool ($10^4 < T < 10^5$ K) gas with $f_{\text{cool}} = 0.11 \pm 0.06$ vs 0.28-0.48 observed of COS-HALOs. Stern et al. (2016) employed new method which have a tight constraint on CGM properties shows a similar result as we predict. To solve this discrepancy may be helpful to answer if current feedback model pushes the gas too far, or puts gas in the wrong
